## Chapter 646

# Meta-Analysis of Tests for the Odds Ratio of Two Proportions using a Random-Effects Model in a Cluster-Randomized Design

## Introduction

This procedure calculates power and number of studies for random-effect meta-analyses of cluster-randomized, two-group studies that are summarized by the odds ratios of two group proportions.

## **Meta-Analysis**

Meta-analysis refers to the systematic assessment of a group of two or more individual studies (experiments or clinical trials). The studies must be similar so that their results may be numerically compared. For example, in this procedure all studies must have as their outcome two group proportions whose odds ratio is used to compare their values.

By combining the results of several studies, their individual results may be summarized and assessed. The power of the combined test will be increased since it represents a larger sample.

#### Fixed-Effects versus Random-Effects Models

The *fixed-effects model*, which is assumed by another procedure, assumes that all studies have the same true effect size. That is, it assumes that all factors that might influence the effect size are the same so that the true effect size for all studies is the same. Therefore, only the *within study variability* needs to be considered since the effect size variation occurs because of random error.

The random-effects model, which is assumed by this procedure, assumes that the studies in the analysis are similar, but not to the extent that they all have the same true effect size. Instead, it is assumed that each study has its own true effect size and that the particular outcome of the study is a sample from a distribution with that proportion. The random-effects model must not only account for the within study variability, but it must also account for the between study variability.

## **Technical Details**

## The Meta-Analysis of the Odds Ratio of Two Proportions

The power formulas used by this procedure are an adaptation of those given in Campbell and Walters (2014), Ahn, Heo, and Zhang (2015), Donner and Klar (2002), Donner, Piaggio, and Villar (2003), and Eldridge and Kerry (2012) page 204.

Cluster-randomized designs are those in which whole clusters of subjects (classes, hospitals, communities, etc.) are randomized into a treatment group or a control group. It is assumed that each study resulted in two group proportions, made up of  $K_i$  clusters of  $M_{ij}$  subjects each, and was analyzed using summary statistics created from the individual subject data. The sample sizes for each study were adjusted to compensate for the cluster-randomization using a *design effect* (DE) factor.

A series of *H* studies are assumed to each have an effect size of *OR* which is the odds ratio of two group proportions. The results of these individual studies may be combined into one overall statistical test that draws a more precise conclusion.

#### **Test Statistic**

Suppose each study has two populations from which dichotomous (binary) responses are recorded. The probability (or risk) of obtaining the event of interest in population 1 (the treatment group) is  $p_1$  and in population 2 (the control group) is  $p_2$ . The corresponding failure proportions are given by  $q_1 = 1 - p_1$  and  $q_2 = 1 - p_2$ .

An assumption is made that the responses from each group follow a binomial distribution. This means that the event probability,  $p_i$ , is the same for all subjects within the group and that the response from one subject is independent of that of any other subject.

Random samples of m and n individuals are obtained from these two populations. The data from these samples can be displayed in a 2-by-2 contingency table as follows

Group	Success	Failure	Total
Treatment	а	С	m
Control	b	d	n
Total	S	f	N

The following alternative notation is sometimes used.

Group	Success	Failure	Total
Treatment	$x_{11}$	$x_{12}$	$n_1$
Control	$x_{21}$	$x_{22}$	$n_2$
Total	$m_1$	$m_2$	N

The binomial proportions,  $p_1$  and  $p_2$ , are estimated from these data using the formulae

$$\hat{p}_1 = \frac{a}{m} = \frac{x_{11}}{n_1}$$
 and  $\hat{p}_2 = \frac{b}{n} = \frac{x_{21}}{n_2}$ 

Meta-Analysis of Tests for the Odds Ratio of Two Prop. using a Random-Effects Model in a Cluster-Randomized Design

#### **Odds Ratio**

Chances are usually communicated as long-term proportions or probabilities. In betting, chances are often given as odds. For example, the odds of a horse winning a race might be set at 10-to-1 or 3-to-2. Odds can easily be translated into probability. An odds of 3-to-2 means that the event is expected to occur three out of five times. That is, an odds of 3-to-2 (1.5) translates to a probability of winning of 0.60.

The odds of an event are calculated by dividing the event risk by the non-event risk. Thus, in our case of two populations, the odds are

$$o_1 = \frac{p_1}{1 - p_1}$$
 and  $o_2 = \frac{p_2}{1 - p_2}$ 

For example, if  $p_1$  is 0.60, the odds are 0.60/0.40 = 1.5. Rather than represent the odds as a decimal amount, it is re-scaled into whole numbers. Instead of saying the odds are 1.5-to-1, we say they are 3-to-2.

Another way to compare proportions is to compute the ratio of their odds. The odds ratio of two events is

$$\psi = \frac{o_1}{o_2} = \frac{p_1 / (1 - p_1)}{p_2 / (1 - p_2)} = \frac{p_1 q_2}{p_2 q_1}$$

Although the odds ratio is more complicated to interpret than the risk ratio or risk difference, it is often the parameter of choice in meta-analyses of proportions because the log odds ratio is normally distributed for moderately sized samples.

## **Meta-Analysis of Proportions**

Suppose the individual tables are summarized into one 2-by-2 table whose individual cells now contain the corresponding cell averages which are still named a, b, c, and d. These counts can be reparametrized using the two group proportions P1 and P2 and the two average-group sample sizes N1 and N2.

These sample sizes are obtained from the cluster-randomized design parameters K1, M1, K2, and M2 using the formulas

$$Ni = \frac{Ki(Mi)}{DE_i}, i = 1,2$$

where

$$DE_1 = 1 + ((COV^2 + 1)M_1 - 1)\rho$$

$$DE_2 = 1 + ((COV^2 + 1)M_2 - 1)\rho$$

These are called the *effective* sample sizes. These adjusted sample sizes can then be used in the regular, two-group formulas given next. The average cell counts are

$$a = (P1)(N1)$$
  
 $b = (P2)(N2)$   
 $c = (1 - P1)(N1)$ 

Using these summary statistics, a summary effect size called the log odds ratio can be calculated using

$$\log(OR) = \log\left(\frac{ad}{bc}\right)$$

along with an estimate of the within-group variance

$$V_W = \frac{1}{a} + \frac{1}{b} + \frac{1}{c} + \frac{1}{d}$$

For planning purposes, the between-group variance is estimated as a multiple of the within-group variance as follows

$$V_R = RV_W$$

Hedges and Pigott (2001) recommend using 0.333 for a *small* value, 0.667 for a *medium* value, and 1.0 for a *large* value of *R*. Note that the fixed-effect results is achieved when *R* is set to 0.

#### I<sup>2</sup> - Heterogeneity Index

Some authors measure the amount of heterogeneity in the meta-analysis using the heterogeneity index  $I^2$  (also called the *degree of heterogeneity* or *inconsistency*) instead of R. This value is related to R as follows. Note that often this value is presented as a percentage.

$$I^2 = \frac{V_B}{V_B + V_W}$$

This value is related to R using the relationship

$$R = \frac{I^2}{1 - I^2}$$

#### Random-Effects Standard Error

The final random-effects standard error used in the power calculation is

$$SE_{\log OR} = \sqrt{\frac{V_W + V_B}{H}}$$

The meta-analysis z-test is then calculated as

$$Z = \frac{\log(OR) - \log(OR_0)}{SE_{\log OR}}$$

We assume that Z follows the standard normal distribution and so it can be used to test the null hypothesis  $H_0$ :  $OR = OR_0$  at significance level of  $\alpha$ .

NCSS.com

## **Hypotheses**

Three statistical hypotheses commonly used are

$$H_0: OR \leq OR_0$$
 vs.  $H_1: OR > OR_0$ 

$$H_0: OR \ge OR_0$$
 vs.  $H_1: OR < OR_0$ 

$$H_0: OR = OR_0$$
 vs.  $H_1: OR \neq OR_0$ 

#### **Power Calculation**

The power of a one-tailed test that  $OR = OR_0$  is given by

$$Power = 1 - \Phi(c_{\alpha} - \lambda)$$

where  $\mathit{OR}$  is set by the alternative hypothesis,  $c_{\alpha}$  is the  $1-\alpha$  quantile of the standard normal distribution, and

$$\lambda = \frac{\log(OR) - \log(OR_0)}{SE_{\log OR}}$$

The power of a two-tailed test that  $OR = OR_0$  is given by

$$Power = 1 - \Phi(c_{\alpha/2} - \lambda) + \Phi(-c_{\alpha/2} - \lambda)$$

These formulas can be used in search algorithms to determine the necessary number of studies required to achieve a desired level of power.

Note that the values of P1.0 (P1 assuming H0) and P1.1 (P1 assuming H1) can be obtained from the odds ratios using

$$P1.0 = \frac{OR_0(P1/(1-P1))}{1 + OR_0(P1/(1-P1))}$$

and

$$P1.1 = \frac{OR_1(P1/(1-P1))}{1 + OR_1(P1/(1-P1))}$$

where  $OR_1$  is the odds ratio at which the power is calculated.

Meta-Analysis of Tests for the Odds Ratio of Two Prop. using a Random-Effects Model in a Cluster-Randomized Design

# **Example 1 – Finding the Number of Studies**

Researchers wish to determine a reasonable number of studies for a meta-analysis with the following characteristics: two-group, equal-allocation trials, two-sided significance level of 0.05, power of 0.9, P2 = 0.5,  $OR_1 = 1.25, 1.5, 1.75$ , and  $OR_0 = 1.0$ . The average number of clusters per study in both groups is 7. The average size of each cluster is 8. The coefficient of variation of cluster sizes is 0.65. The intracluster correlation is 0.05. I2 is used to specify the size of the between study variation. It is set at 0.5.

## Setup

If the procedure window is not already open, use the PASS Home window to open it. The parameters for this example are listed below and are stored in the **Example 1** settings file. To load these settings to the procedure window, click **Open Example Settings File** in the Help Center or File menu.

Meta-Analysis of Tests for the Odds Ratio of Two Prop. using a Random-Effects Model in a Cluster-Randomized Design

#### **Summary Statements**

A collection of two-group cluster-randomized-design studies will be used to test whether the Group 1 proportion is different from the Group 2 proportion (H0: OR = 1 versus H1:  $OR \neq 1$ , OR = odds 1 / odds 2). The meta-analysis comparison will be made using a two-sided random-effects-model Z-test, with a Type I error rate ( $\alpha$ ) of 0.05. In Group 1, the studies are assumed to have an average of 7 clusters with an average of 8 subjects per cluster (totaling 56 subjects), and in Group 2, an average of 7 clusters with an average of 8 subjects per cluster (totaling 56 subjects). The coefficient of variation of the cluster sizes within a group is assumed to be 0.65. The intracluster correlation coefficient of responses within a cluster is assumed to be 0.05. The response proportion of Group 2 (the control group) is assumed to be 0.5. The between-to-total variance ratio ( $I^2$ ), used to calculate the between-study variance, is assumed to be 0.5. To detect an odds ratio ( $I^2$ ) of 1.25 with 90% power, the number of needed studies will be 93.

This report shows the sample sizes for the indicated scenarios.

#### **Plots Section**

This plot represents the required number of studies for various values of OR1.

## **Example 2 – Validation using Hand Calculations**

We could not find a validation example for this procedure in the literature so we will validate the procedure using hand calculations.

Suppose a meta-analysis is contemplated with the following characteristics: two-group, equal-allocation trials, two-sided significance level of 0.05 number of studies = 26, average cluster size of all studies is 15, average number of clusters = 10, COV = 0.65, R=1,  $\rho=0.04, P2=0.5, OR_1=0.1.5$ , and  $OR_0=1.0$ . Calculate the power.

First, we will calculate the power directly using the formulas given above.

**Step 1**: Find the effective sample sizes.

To do this, first calculate the value of DE. The formula for DE is

$$DE = 1 + \{ [COV^2 + 1]\overline{M} - 1 \} \rho$$

Plugging in *COV* = 0.65, M = 15, and  $\rho$  = 0.04 gives

$$DE = 1 + \{[0.65^2 + 1]15 - 1\}(0.04) = 1.8135$$

The effective sample sizes are then found as follows.

$$N1 = N2 = \frac{10(15)}{1.8135} = 82.713$$

**Step 2**: Compute the value of *P*1.

$$P1 = \frac{(OR1)\left(\frac{P2}{1 - P2}\right)}{1 + (OR1)\left(\frac{P2}{1 - P2}\right)} = \frac{1.5}{1 + 1.5} = 0.6$$

Step 3: Compute the average cell counts.

$$a = (P1)(N1) = 0.6(82.713) = 49.6278$$
  
 $b = (P2)(N2) = 0.5(82.713) = 41.3565$   
 $c = (1 - P1)(N1) = 0.4(82.713) = 33.0852$   
 $d = (1 - P2)(N2) = 0.5(82.713) = 41.3565$ 

**Step 4**: Compute the effect size.

$$\log(OR1) = \log(1.5) = 0.4054651$$

**Step 5**: Compute the within-study variance component.

$$V_W = \frac{1}{a} + \frac{1}{b} + \frac{1}{c} + \frac{1}{d} = \frac{1}{49.6278} + \frac{1}{41.3565} + \frac{1}{33.0852} + \frac{1}{41.3565} = 0.098735$$

**Step 6**: Compute the standard error of the effect size.

$$SE_{\log OR} = \sqrt{\frac{V_W + RV_B}{H}} = \sqrt{\frac{0.098735 + 0.098735}{10}} = 0.140524$$

**Step 7**: Compute  $\lambda$ .

$$\lambda = \frac{\log(OR) - \log(OR_0)}{SE_{\log OR}} = \frac{0.4054651 - 0}{0.140524} = 2.8853793$$

**Step 8**: Compute  $c_{\alpha/2}$ .

$$c_{\alpha/2} = \Phi(1 - 0.025) = 1.95996398$$

Step 9: Compute the power.

$$Power = 1 - \Phi(c_{\alpha/2} - \lambda) + \Phi(-c_{\alpha/2} - \lambda)$$

$$= 1 - \Phi(1.95996398 - 2.8853793) + \Phi(-1.95996398 - 2.8853793)$$

$$= 1 - \Phi(-0.9254153) + \Phi(-4.8453433)$$

$$= 1 - 0.17737496 + 0.0000063$$

$$= 0.8226313$$

### Setup

If the procedure window is not already open, use the PASS Home window to open it. The parameters for this example are listed below and are stored in the **Example 2** settings file. To load these settings to the procedure window, click **Open Example Settings File** in the Help Center or File menu.

Solve For	Power
Alternative Hypothesis	Two-Sided (H1: OR ≠ OR0)
Alpha	0.05
H (Number of Studies)	10
K1 (Average Number of Clusters)	10
M1 (Average Cluster Size)	15
K2 (Average Number of Clusters)	K1
M2 (Average Cluster Size)	M1
COV of Cluster Sizes	0.65
OR0 (Odds Ratio H0)	1.0
OR1 (Odds Ratio H1)	1.5
P2 (Group 2 Proportion)	0.5
ρ (Intracluster Correlation, ICC)	0.04
Calculate Between-Study Variance Fro	mR (Between-Study Var / Within-Study Var)
R (Between-Study Var / Within-Study V	ar) <b>1</b>

Meta-Analysis of Tests for the Odds Ratio of Two Prop. using a Random-Effects Model in a Cluster-Randomized Design

## **Output**

Click the Calculate button to perform the calculations and generate the following output.

Solve For: Hypotheses: Calculate Between-Study Variance From:				Power H0: OR = OR0 vs. H1: OR ≠ OR0 R (Between-Study Variance / Within-Study Variance)										
	lahar af	Number of Clusters		Cluster	Size	e Sample Size		Odds Ratio		Proportion		Between vs. Within		
Number of Studies Power H	Average K	Total HK	Average M	cov	Average N	Total HN	OR H1 OR1	OR H0 OR0	P H1 P.1	P H0 P.0	Variance Ratio R	ICC P	Alpha	
0.82263	10	20	200			300	3000	1.5	1					0.05
[Group 1]		10	100	15	0.65	150	1500			0.6	0.5	1	0.04	
[Group 2]		10	100	15	0.65	150	1500			0.5	0.5	1	0.04	

**PASS** also calculates a power of 0.82263 which validates the procedure.
