Chapter 201

Tests for Two Proportions in a Repeated Measures Design

Introduction

This module calculates the power for testing the time-averaged difference (TAD) between two proportions in a repeated measures design. A repeated measures design is one in which subjects are observed repeatedly over time. Measurements may be taken at pre-determined intervals (e.g., weekly or at specified time points following the administration of a particular treatment), or at random times with variable intervals between repeated measurements.

This type of time-averaged difference analysis is often used when the outcome to be measured varies with time. For example, suppose that you want to compare two treatment groups based on a certain binary response variable such as the presence (or absence) of a disease. The disease status may change over time, depending on various factors unrelated to the treatment. The precision of the experiment is increased by taking multiple measurements from each individual and comparing the time-averaged difference in proportions between the two groups. Care must be taken in the analysis because of the correlation that is introduced when several measurements are taken from the same individual. The covariance structure may take on several forms depending on the nature of the experiment and the subjects involved. This procedure allows you to calculate sample sizes and power using four different covariance patterns: Compound Symmetry, AR(1), Banded(1), and Simple.

This procedure can be used to calculate sample size and power for tests of pairwise contrasts in a mixed models analysis of repeated measures data. Mixed models analysis of repeated measures data is also employed to provide more flexibility in covariance specification and a greater degree of robustness in the presence of missing data, provided that the data can be assumed to be missing at random.

Technical Details

Two Test Statistics

This routine has the capability of calculating power and sample size for testing time-averaged difference in proportions based on two different test statistics. The first test statistic is presented in Liu and Wu (2005) and Diggle et al. (1994). The test statistic is based on the difference in proportions:

\[ d = p_1 - p_2, \]

and has the form

\[ z = \frac{\hat{p}_1 - \hat{p}_2}{\sqrt{\text{var}(\hat{p}_1 - \hat{p}_2)}}. \]
The second type of test statistic, presented in Brown and Prescott (2006), has application to mixed models analysis of repeated measures data where there aren’t any random effects other than the subjects themselves, and is based on the difference in proportions defined on the logit link scale:

\[ d = \log(OR) = \log\left(\frac{p_1}{1 - p_1}\right) - \log\left(\frac{p_2}{1 - p_2}\right) = \text{logit}(p_1) - \text{logit}(p_2), \]

and has the form

\[ z = \frac{\text{logit}(\hat{p}_j) - \text{logit}(\hat{p}_h)}{\sqrt{\text{var}(\text{logit}(\hat{p}_j) - \text{logit}(\hat{p}_h))}}. \]

### Testing the Time-Averaged Difference between Two Proportions

#### Theory and Notation

The following derivation is based on the results in Liu and Wu (2005). For a study with \( n_1 \) subjects in group 1, having success proportion \( p_1 \), and \( n_2 \) subjects in group 2, having success proportion \( p_2 \) (for a total of \( N \) subjects), each measured \( m \) times, the time-averaged difference \( (d = p_1 - p_2) \) in proportions between the two groups can be estimated using the following model:

\[
E(y_{ij}|x_{ij}) = \Pr(y_{ij} = 1|x_{ij}) = \beta_0 + \beta_1 x_{ij}, \quad i = 1, \ldots, N; j = 1, \ldots, m,
\]

where

- \( y_{ij} \) is the \( j \)th binary response from subject \( i \),
- \( \beta_0 \) is the model intercept,
- \( \beta_1 \) is the treatment effect or the time-averaged difference in proportions between groups 1 and 2 (i.e., \( \beta_1 = d \)),
- \( x_{ij} \) is a binary group assignment variable, which is equal to 1 if the \( i \)th subject is in group 1 and equal to 0 if the \( i \)th subject is in group 2.

The proportions used to find the difference might be expressed directly as \( p_1 \) and \( p_2 \), or indirectly as \( p_2 \) and an odds ratio

\[ \psi = \frac{p_1(1 - p_1)}{p_2(1 - p_2)} = \frac{p_1 q_2}{p_2 q_1}. \]

The proportion from group 1 can then be computed as

\[ p_1 = \frac{\psi p_2}{1 - p_2 + \psi p_2}. \]
Accounting for the relationship between repeated measurements, the model presented above can be written in matrix form as

$$E(y_i|x_i) = X_i' \beta,$$

where

$$y_i = (y_{i1} \ y_{i2} \ \cdots \ y_{im})'$$

is an \(m \times 1\) vector of responses from subject \(i\),

$$X_i = \begin{pmatrix} 1 & 1 \\ 1 & 1 \\ \vdots & \vdots \\ 1 & 1 \end{pmatrix}_{m \times 2}$$

if the \(i^{th}\) subject is in group 1,

$$X_i = \begin{pmatrix} 1 & 0 \\ 1 & 0 \\ \vdots & \vdots \\ 1 & 0 \end{pmatrix}_{m \times 2}$$

if the \(i^{th}\) subject is in group 2, and

$$\beta = \begin{pmatrix} \beta_0 \\ \beta_1 \end{pmatrix}$$

is the vector of model parameters.

We can stack the data in a single vector and matrix form as follows:

$$y = (y_1', y_2', \ldots, y_N')'$$

$$X = (X_1', X_2', \ldots, X_N')'$$

and the model for the \(N\) equations can be compressed into one as

$$E(y|x) = X' \beta,$$

with

$$V = \text{var}(y) = \sigma^2 \begin{pmatrix} R_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & R_N \end{pmatrix} = \sigma^2 R$$

as the covariance (or variance-covariance) matrix.
Model Estimation

With $\hat{V} = \hat{\sigma}^2 \hat{R}$, then estimates of the regression coefficients from the above regression model are given as

$$\hat{\beta} = \begin{pmatrix} \hat{\beta}_0 \\ \hat{\beta}_1 \end{pmatrix} = (X^\prime \hat{V}^{-1} X)^{-1} X^\prime \hat{V}^{-1} y,$$

and the variance of $\hat{\beta}$ is estimated as

$$\text{var}(\hat{\beta}) = \begin{pmatrix} \text{var}(\hat{\beta}_0) & \text{cov}(\hat{\beta}_0, \hat{\beta}_1) \\ \text{cov}(\hat{\beta}_0, \hat{\beta}_1) & \text{var}(\hat{\beta}_1) \end{pmatrix} = (X^\prime \hat{V}^{-1} X)^{-1} = \sigma^2 (X^\prime \hat{R}^{-1} X)^{-1}.$$

Since the data are binary, the variance term $\sigma^2$ depends on the proportions $p_1$ and $p_2$. Under the null hypothesis, $H_0$, the estimate of $\sigma^2$ is

$$\hat{\sigma}_0^2 = \frac{n_1 p_1 + n_2 p_2}{n_1 + n_2} \left( 1 - \frac{n_1 p_1 + n_2 p_2}{n_1 + n_2} \right) = \frac{(n_1 p_1 + n_2 p_2)(n_1 q_1 + n_2 q_2)}{(n_1 + n_2)^2}$$

where $q_1 = 1 - p_1$ and $q_2 = 1 - p_2$. Under the alternative hypothesis, $H_1$, the estimate of $\sigma^2$ is

$$\hat{\sigma}_1^2 = \frac{n_1}{n_1 + n_2} p_1 q_1 + \frac{n_2}{n_1 + n_2} p_2 q_2 = \frac{n_1 p_1 q_1 + n_2 p_2 q_2}{n_1 + n_2}.$$

The estimated variance of $\hat{\beta}_1$ under the null hypothesis is

$$\text{var}(\hat{\beta}_1 | H_0) = \hat{\sigma}_1^2 = \hat{\sigma}_0^2 [(X^\prime \hat{R}^{-1} X)^{-1}]_{11},$$

and the estimated variance of $\hat{\beta}_1$ under the alternative hypothesis is

$$\text{var}(\hat{\beta}_1 | H_1) = \hat{\sigma}_1^2 = \hat{\sigma}_1^2 [(X^\prime \hat{R}^{-1} X)^{-1}]_{11},$$

where $[A]_{11}$ denotes the lower right-hand element of a $2 \times 2$ matrix, $A$. 
Hypothesis Test

A two-sided test of the null hypothesis that the time-averaged difference in proportions is equal to zero is equivalent to the test of \( H_0: \beta_1 = 0 \) vs. \( H_1: \beta_1 \neq 0 \). Similarly, the upper and lower one-sided tests are \( H_0: \beta_1 \leq 0 \) vs. \( H_1: \beta_1 > 0 \) and \( H_0: \beta_1 \geq 0 \) vs. \( H_1: \beta_1 < 0 \), respectively. The test can be carried out using the test statistic

\[
z = \frac{\hat{\beta}_1}{\sqrt{\text{var}(\hat{\beta}_1)}} = \frac{\hat{p}_1 - \hat{p}_2}{\sqrt{\text{var}(\hat{p}_1 - \hat{p}_2)}} \rightarrow N(0,1).
\]

Power Calculations

Sample sizes for repeated measures studies are often calculated as if a simple trial with no repeated measures was planned, which results in a higher calculated sample size than would be found if the correlation between repeated measures were taken into consideration. With an idea of the correct covariance structure, and an estimate of the within-patient correlation, you can get a better estimate of the power and sample size necessary to achieve your objectives. If you have no indication of the correct covariance structure for the experiment, then the compound symmetry (program default) is likely to be adequate. If you have no previous estimate of the within-patient correlation, then Brown and Prescott (2006) suggest using a conservative prediction of the correlation, i.e., a higher correlation than anticipated.

For a two-sided test where it is assumed that \( d > 0 \) (without loss of generality),

\[
\text{Power} = 1 - \beta = \Pr(\text{rejecting } H_0 | H_1)
\]

\[
= \Pr \left( \left| \frac{\hat{\beta}_1}{\sqrt{\text{var}(\hat{\beta}_1)}} \right| > z_{1-\alpha/2} | H_1 \right)
\]

\[
\approx \Pr \left( \frac{\hat{\beta}_1}{\sqrt{\text{var}(\hat{\beta}_1)}} > z_{1-\alpha/2} | H_1 \right) \text{ since it is assumed that } d > 0
\]

\[
= \Pr \left( \frac{\hat{\beta}_1 - d}{\hat{\sigma}_{\beta_1,H_0}} > z_{1-\alpha/2} - \frac{d}{\hat{\sigma}_{\beta_1,H_0}} | H_1 \right)
\]

\[
= \Pr \left( \frac{\hat{\beta}_1 - d}{\hat{\sigma}_{\beta_1,H_1}} > \frac{\hat{\sigma}_{\beta_1,H_0}}{\hat{\sigma}_{\beta_1,H_0}} \cdot z_{1-\alpha/2} - \frac{d}{\hat{\sigma}_{\beta_1,H_0}} | H_1 \right)
\]

\[
= \Pr \left( \frac{\hat{\beta}_1 - d}{\hat{\sigma}_{\beta_1,H_1}} > \frac{\hat{\sigma}_{\beta_1,H_0}}{\hat{\sigma}_{\beta_1,H_1}} \cdot z_{1-\alpha/2} - \frac{d}{\hat{\sigma}_{\beta_1,H_1}} | H_1 \right)
\]

\[
= 1 - \Phi \left( \frac{\hat{\sigma}_{\beta_1,H_0}}{\hat{\sigma}_{\beta_1,H_1}} \cdot z_{1-\alpha/2} - \frac{d}{\hat{\sigma}_{\beta_1,H_1}} \right),
\]
where $\Phi()$ is the standard normal density function, and $\alpha$ and $\beta$ are the probabilities of type I and type II error, respectively. For a one-sided test, $\alpha$ is used in place of $\alpha/2$.

**Testing Two Proportions using the Time-Averaged Difference defined on the Logit Link Scale (Testing Pairwise Contrasts of Fixed Effects in Mixed Models)**

**Mixed Models Theory and Notation**

The following derivation is based on the results in Brown and Prescott (2006) and Liu and Wu (2005). A generalized linear mixed model incorporates both fixed and random effects. Fixed effects are those effects in the model whose values are assumed constant, or unchanging. Random effects are those effects in the model that are assumed to have arisen from a distribution, resulting in another source of random variation other than residual variation. For an experiment with $N$ subjects, $p$ fixed effect parameters, and $q$ random effect parameters, the generalized linear mixed model can be expressed using matrix notation as

$$y_i = \mu_i + \varepsilon_i, \quad i = 1, \ldots, N$$

where

- $y_i$ is an $n_i \times 1$ vector of responses for subject $i$,
- $\mu_i$ is an $n_i \times 1$ vector of expected means for subject $i$, and is linked to the model parameters by a link function, $g$:

$$g(\mu_i) = \text{logit}(\mu_i) = \left( \begin{array}{c} \log(\pi_i/(1 - \pi_i)) \\ \vdots \\ \log(\pi_i/(1 - \pi_i)) \end{array} \right)_{n_i \times 1} = X_i \beta + Z_i u_i, \quad i = 1, \ldots, N$$

where

- $\pi_i$ is the probability of success from a bernoulli distribution for individual $i$,
- $X_i$ is an $n_i \times p$, full-rank design matrix of fixed effects for subject $i$,
- $\beta$ is a $p \times 1$ vector of fixed effects parameters,
- $Z_i$ is an $n_i \times q$ design matrix of the random effects for subject $i$,
- $u_i$ is a $q \times 1$ vector of random effects for subject $i$ which has means of zero and scaled covariance matrix $G$,
- $\varepsilon_i$ is an $n_i \times 1$ vector of errors for subject $i$ with zero mean and scaled covariance $\Sigma_i$.

© NCSS, LLC. All Rights Reserved.
We can stack the data in a single vector and matrix form as follows:

\[ y = (y_1, y_2, \ldots, y_N)' \]
\[ \mu = (\mu_1, \mu_2, \ldots, \mu_N)' \]
\[ X = (X_1, X_2, \ldots, X_N)' \]
\[ Z = \begin{pmatrix} Z_1 & 0 & 0 \\
0 & \ddots & 0 \\
0 & 0 & Z_N \end{pmatrix} \]
\[ u = (u_1, u_2, \ldots, u_N)' \]
\[ \varepsilon = (\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_N)' \]

and the mixed model for the \( N \) equations can be compressed into one as

\[ y = \mu + \varepsilon \]

with

\[ g(\mu) = \log \text{it} (\mu) = X\beta + Zu. \]

The covariance of \( y, \text{var}(y) = V \), can then be written as

\[ V = \begin{pmatrix} V_1 & 0 & 0 \\
0 & \ddots & 0 \\
0 & 0 & V_N \end{pmatrix} \]

\[ = \text{var}(\mu + \varepsilon) \]
\[ = \text{var}(\mu) + \Sigma \]
\[ \approx BZGZ'B + B^{1/2}RB^{1/2}, \]

where

\[ B = \begin{pmatrix} \pi_1(1-\pi_1) & 0 & 0 & 0 \\
0 & \pi_2(1-\pi_2) & 0 & 0 \\
0 & 0 & \ddots & \vdots \\
0 & 0 & \cdots & \pi_N(1-\pi_N) \end{pmatrix} \]

\( R \) is the correlation matrix defined on the linear scale.
Mixed Models Estimation

In order to fit the generalized linear mixed model, a pseudo-variable \( z \) must be introduced to transform \( y \) onto the linear scale. More specifically,

\[
z = g(\mu) + (y - \mu)B^{-1} = X\beta + Zu + (y - \mu)B^{-1}
\]

and \( z \) has variance

\[
V_z = \text{var}(X\beta + Zu) + B^{-1}\text{var}(y - \mu)B^{-1} = ZGZ' + B^{-1/2}RB^{-1/2}
\]

If \( ZG' = 0 \) (which is the case when no random effects are included in the model), then

\[
V_z = B^{-1/2}RB^{-1/2}.
\]

Estimates of the variance components are found using maximum likelihood (ML) or restricted/residual maximum likelihood (REML) methods. The fixed effects are then estimated as

\[
\hat{\beta} = (X'V_z^{-1}X)^{-1}X'V_z^{-1}y
\]

with the variance estimated as

\[
\text{var}(\hat{\beta}) = (X'V_z^{-1}X)^{-1}
\]

These estimation equations are nearly identical to the TAD estimation equations presented earlier, except for the fact that \( \beta \) may contain more than two parameters, i.e., a parameter for each fixed effect being modeled. In the TAD model presented above, \( \beta_1 \) represents the difference between two treatment proportions. In the generalized mixed model formulation presented here, \( \beta_1, \beta_2, \text{etc.} \) represent individual proportions defined on the logit link scale.

Testing Fixed Effects

Significance tests for fixed or random effects can be done using tests based on the \( t \) distribution. We can define tests of fixed and random effects as contrasts

\[
C = L'\hat{\beta} = 0,
\]

respectively. For example, in a trial containing three treatments A, B, and C, a pairwise comparison of treatments A and C is given by the contrast

\[
C_{AC} = L'\hat{\beta} = (0\ 1\ 0\ -1)\hat{\beta} = \hat{\beta}_A - \hat{\beta}_C,
\]

where the first term in \( \hat{\beta} \) is the intercept term, and the other three terms are the treatment effects.
For a single comparison, the Wald test statistic is given by

\[
z = \frac{\mathbf{L}' \hat{\beta}}{\sqrt{\text{var}(\mathbf{L}' \hat{\beta})}}
\]

\[
= \frac{\hat{\beta}_j - \hat{\beta}_h}{\sqrt{\text{var}(\hat{\beta}_j - \hat{\beta}_h)}}
\]

\[
= \frac{\logit(\hat{p}_j) - \logit(\hat{p}_h)}{\sqrt{\text{var}(\logit(\hat{p}_j) - \logit(\hat{p}_h))}} \rightarrow N(0,1),
\]

where \(\hat{\beta}_j\) and \(\hat{\beta}_h\) (\(j \neq h\)) are estimated treatment effects defined on the logit link scale and \(p_j\) and \(p_h\) are the proportions from groups \(j\) and \(h\), respectively.

Since the data are binary, \(\text{var}(\hat{\beta}_j - \hat{\beta}_h)\) depends on the proportions \(p_j\) and \(p_h\). Under the null hypothesis, \(H_0\), the estimate of \(\text{var}(\hat{\beta}_j - \hat{\beta}_h)\) is

\[
\text{var}(\hat{\beta}_j - \hat{\beta}_h | H_0) = \sigma^2_{\hat{\beta}_j - \hat{\beta}_h,H_0}
\]

\[
= \mathbf{L}' (\mathbf{X} \mathbf{V}_z^{-1} \mathbf{X})^{-1} \mathbf{L}
\]

\[
= \frac{(n_j + n_h)^2}{(n_j p_j + n_h p_h)(n_j q_j + n_h q_h)} \mathbf{L}'(\mathbf{X} \mathbf{R}_1^{-1} \mathbf{X})^{-1} \mathbf{L},
\]

where \(q_k = 1 - p_k\). Under the alternative hypothesis, \(H_1\), the estimate of \(\text{var}(\hat{\beta}_j - \hat{\beta}_h)\) is

\[
\text{var}(\hat{\beta}_j - \hat{\beta}_h | H_1) = \sigma^2_{\hat{\beta}_j - \hat{\beta}_h,H_1}
\]

\[
= \mathbf{L}' (\mathbf{X} \mathbf{V}_z^{-1} \mathbf{X})^{-1} \mathbf{L}
\]

\[
= \frac{n_j + n_h}{n_j p_j q_j + n_h p_h q_h} \mathbf{L}'(\mathbf{X} \mathbf{R}_1^{-1} \mathbf{X})^{-1} \mathbf{L}.
\]

In practice, the test is often performed using software containing generalized linear models capability, such as SAS® PROC GLIMMIX or SAS® PROC GENMOD with a REPEATED statement. The test of the difference in proportions is generated with an estimation statement such as

\[
\text{ESTIMATE 'A-C' treat 1 0 -1; or LSMEANS treat/ PDIFF;}
\]
The latter statement would produce tests of all pairwise comparisons of the levels of the treatment variable, defined on the logit link scale. The former would only test the difference between groups A and C. Of course, these comparison statements must be used in conjunction with appropriate model and class statements.

**Power Calculations**

Sample sizes for repeated measures studies are often calculated as if a simple trial with no repeated measures was planned, which results in a higher calculated sample size than would be found if the correlation between repeated measures were taken into consideration. With an idea of the correct covariance structure, and an estimate of the within-patient correlation, you can get a better estimate of the power and sample size necessary to achieve your objectives. If you have no indication of the correct covariance structure for the experiment, then the compound symmetry (program default) is likely to be adequate. If you have no previous estimate of the within-patient correlation, then Brown and Prescott (2006) suggest using a conservative prediction of the correlation, i.e., a higher correlation than anticipated.

For a two-sided test where it is assumed that \( \hat{\beta}_j - \hat{\beta}_h > 0 \) (without loss of generality),

\[
\text{Power} = 1 - \beta = \Pr(\text{rejecting } H_0|H_1) = \Pr\left( \left| \frac{\hat{\beta}_j - \hat{\beta}_h}{\text{var}(\hat{\beta}_j - \hat{\beta}_h)} \right| > z_{1-\alpha/2}|H_1 \right)
\]

\[
\approx \Pr\left( \frac{\hat{\beta}_j - \hat{\beta}_h}{\sqrt{\text{var}(\hat{\beta}_j - \hat{\beta}_h)}} > z_{1-\alpha/2}|H_1 \right) \text{ since it is assumed that } d > 0
\]

\[
= \Pr\left( \frac{\hat{\beta}_1 - d}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,0}} > z_{1-\alpha/2} - \frac{d}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,0}|H_1} \right)
\]

\[
= \Pr\left( \frac{\hat{\beta}_j - \hat{\beta}_h - d \cdot \hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,1}}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,0}} > z_{1-\alpha/2} - \frac{d}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,0}|H_1} \right)
\]

\[
= \Pr\left( \frac{\hat{\beta}_1 - d}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,1}} > \frac{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,0}}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,1} \cdot z_{1-\alpha/2} - \frac{d}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,1}|H_1} \right)
\]

\[
= 1 - \Phi\left( \frac{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,0}}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,1} \cdot z_{1-\alpha/2} - \frac{d}{\hat{\sigma}_{\hat{\beta}_j-\hat{\beta}_h,1}|H_1} \right)
\]

where \( \Phi() \) is the standard normal density function, and \( \alpha \) and \( \beta \) are the probabilities of type I and type II error, respectively. For a one-sided test, \( \alpha \) is used in place of \( \alpha/2 \).
Covariance Patterns

In a repeated measures design with \( N \) subjects, each measured \( m \) times, observations from a single subject may be correlated and a pattern for their covariance is specified. In this case, \( V \) will have a block-diagonal form and can be written as

\[
V = \sigma^2 R = \begin{pmatrix}
V_1 & 0 & 0 & \cdots & 0 \\
0 & V_2 & 0 & \cdots & 0 \\
0 & 0 & V_3 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & V_N
\end{pmatrix}
\]

where \( V_i \) are \( m \times m \) covariance matrices corresponding to the \( i^{th} \) subject. The 0's represent \( m \times m \) matrices of zeros giving zero covariances for observations on different subjects. This routine allows the specification of four different covariance matrix types: Compound Symmetry, AR(1), Banded(1), and Simple.

**Compound Symmetry**

A compound symmetry covariance model assumes that all covariances are equal, and all variances on the diagonal are equal. That is

\[
V_i = \sigma^2 \begin{pmatrix}
1 & \rho & \rho & \rho & \cdots & \rho \\
\rho & 1 & \rho & \rho & \cdots & \rho \\
\rho & \rho & 1 & \rho & \cdots & \rho \\
\rho & \rho & \rho & 1 & \cdots & \rho \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\
\rho & \rho & \rho & \rho & \cdots & 1
\end{pmatrix}_{m \times m}
\]

where \( \sigma^2 = \text{var}(y_{ij}) \) and \( \rho \) is the correlation between observations on the same subject.

**AR(1)**

An AR(1) (autoregressive order 1) covariance model assumes that all variances on the diagonal are equal and that covariances \( t \) time periods apart are equal to \( \sigma^2 \rho^t \). That is

\[
V_i = \sigma^2 \begin{pmatrix}
1 & \rho & \rho^2 & \rho^3 & \cdots & \rho^{m-1} \\
\rho & 1 & \rho & \rho^2 & \cdots & \rho^{m-2} \\
\rho^2 & \rho & 1 & \rho & \cdots & \rho^{m-3} \\
\rho^3 & \rho^2 & \rho & 1 & \cdots & \rho^{m-4} \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\
\rho^{m-1} & \rho^{m-2} & \rho^{m-3} & \rho^{m-4} & \cdots & 1
\end{pmatrix}_{m \times m}
\]

where \( \sigma^2 = \text{var}(y_{ij}) \) and \( \rho \) is the correlation between observations on the same subject.
Banded(1)

A Banded(1) (banded order 1) covariance model assumes that all variances on the diagonal are equal, covariances for observations one time period apart are equal to $\sigma^2 \rho$, and covariances for measurements greater than one time period apart are equal to zero. That is

$$
V_i = \sigma^2 \begin{pmatrix}
1 & \rho & 0 & 0 & \cdots & 0 \\
\rho & 1 & \rho & 0 & \cdots & 0 \\
0 & \rho & 1 & \rho & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & 0 & \cdots & 1 \\
\end{pmatrix}_{m \times m}
$$

where $\sigma^2 = \text{var}(y_{ij})$ and $\rho$ is the correlation between observations on the same subject.

Simple

A simple covariance model assumes that all variances on the diagonal are equal and that all covariances are equal to zero. That is

$$
V_i = \sigma^2 \begin{pmatrix}
1 & 0 & 0 & 0 & \cdots & 0 \\
0 & 1 & 0 & 0 & \cdots & 0 \\
0 & 0 & 1 & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & 0 & \cdots & 1 \\
\end{pmatrix}_{m \times m}
$$

where $\sigma^2 = \text{var}(y_{ij})$. 
Example 1 – Determining Power

A study is being planned to determine the efficacy of a prophylactic treatment for the common cold. The study will follow a treatment group and placebo control group through the winter to determine if there is an overall difference between the two treatment groups in the proportion of patients who get sick. Subjects will take the treatment (or placebo) once daily throughout the duration of the study. The study will be conducted from September to April with scheduled, monthly visits (beginning in October) to determine the patient's disease status (present or absent). Therefore, a total of seven responses will be observed for each patient. Previous studies have indicated a baseline disease rate of 60% for the common cold. The researchers want to be able to detect a treatment to control odds ratio of 0.5 (an odds ratio of 0.5 corresponds to a treatment group proportion of 0.4285714). A compound-symmetry covariance pattern with autocorrelation of 0.5 is assumed to be adequate. The test will be conducted using a mixed models analysis with an alpha level of 0.05.

What power does the study achieve over a range of possible sample sizes?

Setup

If the procedure window is not already open, use the PASS Home window to open it. The parameters for this example are listed below and are stored in the Example 1 settings file. To load these settings to the procedure window, click Open Example Settings File in the Help Center or File menu.

```
Design Tab

Solve For .................................................... Power
Test Statistic Based on .........................Log(OR): logit(P1)-logit(P2)
Alternative Hypothesis .......................Two-Sided

</table>

Power The probability of rejecting a false null hypothesis when the alternative hypothesis is true.
N1 and N2 The number of items sampled from each population.
N The total sample size. N = N1 + N2.
M The number of time points (repeated measurements) at which each subject is observed.
P1 and P2 The proportions from groups 1 and 2, respectively.
OR1 The odds ratio ((P1/(1-P1))/(P2/(1-P2))) to be detected.
Rho The correlation between observations on the same subject.
Alpha The probability of rejecting a true null hypothesis.

Summary Statements

A parallel two-group repeated-measures design with 7 measurements on each subject will be used to test whether the Group 1 (treatment) proportion (P1) is different from the Group 2 (control) proportion (P2). The comparison will be made using a two-sided, two-sample time-averaged difference in logit proportions test (from a generalized linear mixed model formulation) as in Brown and Prescott (2006) and Liu and Wu (2005). The Type I error rate (α) is to be 0.05. The control group proportion (P2) is assumed to be 0.6. The covariance structure for repeated observations on the same subject is Compound Symmetry, with a correlation between observations on the same subject (autocorrelation) of 0.5. To detect a Group 1 (treatment) proportion (P1) of 0.429 (or odds ratio of 0.5), with sample sizes of 10 for Group 1 (treatment) and 10 for Group 2 (control), the power is 0.17843.

### Dropout Summary Statements

Anticipating a 20% dropout rate, 13 subjects should be enrolled in Group 1, and 13 in Group 2, to obtain final group sample sizes of 10 and 10, respectively.

### References

This report gives the power for each value of the other parameters.

### Power

This is the computed power for detecting the time-averaged difference between the two group means.

#### Group 1 Sample Size (N1)

The value of N1 is the number of subjects in group 1.

#### Group 2 Sample Size (N2)

The value of N2 is the number of subjects in group 2.
Time Points (M)
This is the number of repeated measurements taken.

Group 1 Prop (P1) & Group 2 Prop (P2)
These are the proportions of successes in groups 1 and 2, respectively.

Odds Ratio (OR1)
This is the value of the odds ratio under the alternative hypothesis.

Autocorr. (Rho)
This is the correlation between observations from the same subject.

Alpha
Alpha is the significance level of the test.

Beta
Beta is the probability of failing to reject the null hypothesis when the alternative hypothesis is true.

Plots Section

The chart shows the relationship between power and \( N1 \) when the other parameters in the design are held constant.
Example 2 – Finding the Sample Size

Continuing with Example 1, the researchers want to determine the exact sample size necessary to achieve at least 80% power.

Setup

If the procedure window is not already open, use the PASS Home window to open it. The parameters for this example are listed below and are stored in the Example 2 settings file. To load these settings to the procedure window, click Open Example Settings File in the Help Center or File menu.

</tbody>
</table>

A group sample size of 76 is required to achieve at least 80% power.
Example 3 – Varying the Odds Ratio

Continuing with Examples 1 and 2, the researchers want to evaluate the impact on power of varying the odds ratio from 0.4 to 0.8.

Setup

If the procedure window is not already open, use the PASS Home window to open it. The parameters for this example are listed below and are stored in the Example 3 settings file. To load these settings to the procedure window, click Open Example Settings File in the Help Center or File menu.

These charts show how the power depends on the proportion, $P_1$, as well as the group sample size $N_1$. 
Example 5 – Impact of the Number of Repeated Measurements

Continuing with Example 2, the researchers want to study the impact on the sample size if they change the number of measurements made on each individual. Their experimental protocol calls for seven measurements. They want to see the impact of taking twice that many measurements.

Setup

If the procedure window is not already open, use the PASS Home window to open it. The parameters for this example are listed below and are stored in the Example 5 settings file. To load these settings to the procedure window, click Open Example Settings File in the Help Center or File menu.

Design Tab

<table>

<td>0.5</td>
<td>0.5</td>
<td>0.05</td>
</tr>
</tbody>
</table>

Doubling the number of repeated measurements per individual decreases the group sample size by only 5 individuals. This reduction in sample size may not justify the additional seven trips to the clinic for each subject.
Example 6 – Validation using Diggle et al. (1994)

Diggle et al. (1994) pages 31 and 32 present an example of calculating the sample size for a TAD study. They calculate the group sample sizes for the cases where the difference in proportions \(P_1 - P_2\) ranges from 0.1 to 0.3, \(\rho\) ranges from 0.2 to 0.8, alpha = 0.05, \(p_2 = 0.5\), \(M = 3\), and power = 0.8. Note that Diggle et al (1994) uses a one-sided test and the test statistic based on the difference in proportions.

To calculate the sample sizes using the odds ratio specification, we must first convert the differences to odds ratios using the formula:

\[
OR = \frac{P_1/(1 - P_1)}{P_2/(1 - P_2)}
\]

Differences of 0.1, 0.2, and 0.3 with \(P_2 = 0.5\) correspond to odds ratios of 1.5, 2.333, and 4.0, respectively.

Setup

If the procedure window is not already open, use the PASS Home window to open it. The parameters for this example are listed below and are stored in the Example 6 settings file. To load these settings to the procedure window, click Open Example Settings File in the Help Center or File menu.

The sample sizes calculated by PASS match the results of Diggle et al. (1994) exactly.

Brown and Prescott (2006) page 270 presents an example of calculating the sample size for a future study. They calculate the group sample size to be 85 for a future study involving four post-treatment visits to detect a doubling of the odds ratio (i.e., OR1 = 2) at the 5% significance level with 80% power. They assume an autocorrelation of 0.5, and an expected rate of positives ((P1+P2)/2) of 0.4. We can calculate the corresponding values of P1, P2, and OR for use in PASS by solving the following system of equations for P1 and P2:

\[
\frac{P_1 + P_2}{2} = 0.4 \quad \text{and} \quad \frac{P_1/(1-P_1)}{P_2/(1-P_2)} = OR = 2.0
\]

The solution to these equations occurs when P1 = 0.482255312124 and P2 = 0.317744687876. The decimal places are kept to make the solution exact.

Setup

If the procedure window is not already open, use the PASS Home window to open it. The parameters for this example are listed below and are stored in the Example 7 settings file. To load these settings to the procedure window, click Open Example Settings File in the Help Center or File menu.

The sample size of 86 calculated by PASS matches the results of Brown and Prescott (2006). The slight difference is due to rounding. Calculation of the sample size presented by Brown and Prescott (2006) on page 270 results in a value of 85.025337, which they round down to 85. Note that the numerical formula has a typographical error: the denominator term should be \(4 \times .693^2\), not \(4 \times .693^2\) (see the formula on page 269 of Brown and Prescott (2006)).
